Abstract

New transparent CeO₂:Ln (Ln = Eu³⁺ or Sm³⁺) thin-film phosphors have been fabricated by a sol-gel method. Homogeneous precursor solutions, with Ln concentrations varied between 0.05 and 100 at.%, were obtained by dissolving a mixture of pertinent metal acetates and trifluoroacetic acid in ethanol. The solutions were deposited on silica glass substrates by spin-coating and then heated at 700°C in air. Fluorite-type crystalline phases were formed in all the films, although their chemical compositions seemed to change from CeO₂:Ln to LnOF depending on the Ln concentration. CeO₂:Ln films with the Ln concentrations of 1 at.% showed the strongest photoluminescence (PL) upon ultraviolet (UV) light excitation. At higher Ln concentrations, the PL intensity decreased because of the nonradiative energy transfer between Ln ions as luminescent centers. For Eu³⁺ ions doped in the CeO₂ lattice with inversion symmetry, an orangish red emission due to a magnetic-dipole ${}^{5}D_{0} \rightarrow {}^{7}F_{1}$ transition (591 nm) was dominant without other strong ${}^{5}D_{0}$ -related emissions when excited at a wavelength of 340 nm. In contrast, much stronger orange emissions (573 nm) due to ${}^{4}G_{5/2} \rightarrow {}^{6}H_{5/2}$ were observed for Sm³⁺ ions. Apparently, the Eu³⁺ and the Sm³⁺ ions had different

efficiencies of the excitation through the energy transfer from the " $Ce^{4+}-O^{2-}$ " charge transfer state induced by the UV irradiation.

1. Introduction

Recent progress in ultraviolet light emitting diodes (UVLEDs) has opened possibility of designing new opto-electronic devices.¹ UV-pumped phosphors are one of the key materials for development of such devices. Luminescence from rare-earth (RE) ions based on intraconfigurational electronic transitions shows a sharp spectrum, which is useful for applications as phosphors in display devices, lighting devices, solid-state lasers, etc. When combined with UVLEDs, phosphors should be in a thin-film form and provide advantages such as high emission efficiencies, good compatibility with semiconductor devices, and low fabrication cost. Furthermore, the excitation at near-UV wavelengths is preferable to the use of LEDs as light source.

It has been reported that RE-doped Sr_2CeO_4 materials exhibit excellent luminescent properties.²⁻⁴ The excitation of Sr_2CeO_4 :RE is supposed to originate from the initial "Ce⁴⁺–O^{2–}" charge-transfer (CT) transition in the host lattice absorbing the excitation light. An efficient energy transfer can then occur from the "Ce⁴⁺–O^{2–}" CT state (CTS) to the doped trivalent RE ions having CT excited states (the sensitizer-activator relation) through a non-resonance process involving the exchange interaction.³ As to cerium dioxide (CeO₂), however, few works have been reported on luminescence of the doped RE ions, although it can exhibit strong UV light absorption through the CT from O^{2–} to Ce⁴⁺. In addition to this attractive character, CeO₂ has both thermal and chemical stability and can be easily deposited on substrates as thin films even at lower heat-treatment temperatures. Recently, we have

succeeded in fabricating novel thin-film phosphors based on CeO₂:Ln (Ln = Eu³⁺ and Sm³⁺) by a sol-gel method.⁵ It was found that Sm³⁺ doped in CeO₂ at the doping level of 1 at.% caused unusual strong ${}^{4}G_{5/2} \rightarrow {}^{6}H_{5/2}$ emissions exhibiting orange color. In this paper, the effects of dopant concentrations on optical properties of CeO₂:Ln were investigated to improve their luminescent properties. Luminescence of Eu³⁺ was also discussed by comparing host lattice of CeO₂ and EuOF having the similar fluorite-type structure.

2. Experimental procedure

Eu³⁺ and Sm³⁺ doped CeO₂ thin films were prepared by a sol-gel method using RE acetates. Precursor solutions for CeO₂ were prepared by dissolving Ce(CH₃COO)₃·H₂O and trifluoroacetic acid (TFA; CF₃COOH) in ethanol. Separately, Eu(CH₃COO)₃·4H₂O or Sm(CH₃COO)₃·4H₂O were dissolved in ethanol with addition of TFA. The overall metal concentration was adjusted to 0.25M. Coating solutions were prepared by mixing these solutions and stirring for 24 h at room temperature. Dopant concentrations in CeO₂ were changed between 0.05 and 100 at.%. The resultant coating solutions were spin-coated on quartz glass substrates and heated at 700°C for 10 min in air. This coating/heating procedure was repeated three times to increase the film thickness.

Phase identification of the films was performed with an X-ray diffractometer equipped with a thin-film attachment using CuK α radiation (Rigaku). Optical transmission/absorption spectra were recorded with a UV-visible spectrophotometer (Hitachi, type U-3300). Photoluminescence (PL) spectra were measured at room temperature with a spectrofluorophotometer (Shimadzu, type RF-5300PC) using a Xe lamp (150 W) as a light source. A filter was used to remove a second-order peak of the excitation light in the PL measurement.

3. Results and Discussion

Two different crystal structures were formed in the CeO₂:Eu³⁺ films depending on the Eu³⁺ concentration, as suggested by the X-ray diffraction (XRD) analysis. Figure 1 shows the XRD patterns for the films containing 1.00–100 at.% of Eu³⁺. Diffraction peaks of the films with 1.00–30.0 at.% of Eu³⁺ can be indexed with a cubic CeO₂ structure (JCPDS No. 34-394). On the other hand, we can index a diffraction peaks of the film of 100 at.% of Eu³⁺ as a cubic EuOF structure (JCPDS No. 26-635). The structural change was further supported by the transmission spectra. As shown in Fig. 2, transmittance of the CeO₂:Eu³⁺ films (0–30 at.% of Eu³⁺) decreases in the UV region below approximately 360 nm, indicative of the inter-band absorption of CeO₂. In contrast, the EuOF film (corresponding to 100 at.% of Eu³⁺) exhibits an absorption edge at a much shorter wavelength of approximately 290 nm, which is attributed to electronic transitions between the O 2p and the Eu 4f levels.

PL was appreciably observed only for the films with the lower Eu³⁺ concentration between 0.05–10.0 at.% at an excitation wavelength of 340 nm. This result is similar to that reported for the Sr₂CeO₄ system.³ From the PL spectra of the CeO₂:Eu³⁺ films shown in Fig. 3, it was found that an orangish red emission due to a magnetic-dipole ${}^{5}D_{0} \rightarrow {}^{7}F_{1}$ transition (591 nm) of Eu³⁺ was dominant without other strong ${}^{5}D_{0}$ -related emissions. The fluorite-type CeO₂ structure has the high inversion symmetry of Ce sites; thereby a forbidden electricdipole ${}^{5}D_{0} \rightarrow {}^{7}F_{2}$ transition cannot be observed. The emission intensity from the film containing 1.00 at.% of Eu³⁺ was strongest in the present CeO₂:Eu³⁺ system. With the higher Eu³⁺ concentrations of 20.0–100 at.%, the emission was relatively weakened due to occurrence of a non-radiative energy transfer between the luminescent center.⁶

For the excitation wavelength of 340 nm used above, no emission was detected for the EuOF film. Upon the excitation at 259 nm, however, strong red emissions were observed from the Eu^{3+} ions in EuOF. PL spectra of $CeO_2:Eu^{3+}$ and EuOF are compared in Fig. 4 with

the excitation at 331 and 259 nm, respectively. The dominant emissions from EuOF are centered at 610 and 624 nm. It is known that EuOF has no inversion symmetry in the Eu³⁺ sites, providing much higher probability of the hypersensitive ${}^{5}D_{0} \rightarrow {}^{7}F_{2}$ transitions.⁷

PL excitation (PLE) spectra of the CeO₂:Eu³⁺ film (1 at.% of Eu³⁺) for the 591 nm emission and those of the EuOF film for the 610 nm emission are shown in Fig. 5 together with their absorption spectra. A broad-band excitation peak centered at 330 nm is observed in the PLE spectra of Fig. 5(a). An absorption edge observed in the absorption spectrum, approximately 360 nm, corresponds to a band-gap of CeO₂ reported as 3.4 eV (365 nm).⁸ EuOF shows, on the other hand, a narrower excitation band centered at 260 nm (Fig 5(b)). In addition, the absorption spectrum of EuOF shows an absorption edge around 280 nm, as described above for the transmission spectra. These spectral data support that the efficient energy transfer from the "Ce⁴⁺–O^{2–3}" CTS to the doped Eu³⁺ could be achieved in the CeO₂:Eu³⁺ system.

Figure 6 shows PL and PLE spectra of the CeO₂:Sm³⁺ film at the dopant level of 1.00 at.%. The structure of the PLE spectra for the CeO₂:Sm³⁺ film is similar to that of the CeO₂:Eu³⁺ film shown in Fig. 5(a), suggesting the same excitation mechanism. The PL spectra show orange emissions (with the strongest peak at 573 nm) due to the ${}^{4}G_{5/2} \rightarrow {}^{6}H_{5/2}$ transition of Sm³⁺. The intensity of the 573 nm emission of Sm³⁺ was observed to be four times higher than that of the 590 nm emission of Eu³⁺ at the same dopant level of 1.00 at.%. The different emission intensities between Eu³⁺ and Sm³⁺ can be explained as follows. The excitation of CeO₂:Ln is supposed to originate from the initial "Ce⁴⁺–O^{2–}" CT transition in the host lattice absorbing the excitation light. Then the efficient energy transfer can occur from the "Ce⁴⁺–O^{2–}" CTS to the doped Eu³⁺ or Sm³⁺ ions having CT excited states. The Eu³⁺ and the Sm³⁺ ions may have different efficiencies of the energy transfer from the "Ce⁴⁺–O^{2–}" CTS, which leads to the different overall excitation efficiency.

4. Conclusions

A series of transparent and luminescent thin films, namely CeO₂:Ln (Ln = Eu³⁺ and Sm³⁺) and EuOF, were fabricated by the sol-gel method. In the fluorite-type CeO₂ host, photoluminescence was observed only for the films with the lower Ln concentrations. The orangish red emissions (591 nm) due to the magnetic-dipole ${}^{5}D_{0} \rightarrow {}^{7}F_{1}$ transition of Eu³⁺ was dominant without other strong ${}^{5}D_{0}$ -related emissions at the excitation wavelength of 340 nm in the CeO₂:Eu³⁺ films. This is because CeO₂ provides inversion symmetry with the doped Eu³⁺ site. The CeO₂:Sm³⁺ showed the orange emissions (573 nm), the intensity of which was much higher than that of the emission from Eu³⁺, due to the ${}^{4}G_{5/2} \rightarrow {}^{6}H_{5/2}$ transitions. The excitation mechanism was suggested to be the energy transfer from the "Ce⁴⁺–O^{2–}" CTS to the doped Eu³⁺ and Sm³⁺ ions.
